1 Introduction

This review deals with the concept of complementarity for diploid genomes, which was presumably first found in computer simulations [1] similar to the old bit-string model of biological ageing [2, 3]. We hope that this review (partially taken from [4]) will encourage experimental biologists to look for such effects in reality. Presumably this complementarity is more likely found in small populations with low recombination rates during sexual reproduction, and mostly recessive instead of dominant mutations (our mutations are regarded as detrimental, causing hereditary diseases).

Usually Darwinian selection is thought to lower the number of detrimental mutations, but due to copying errors and other reasons new inheritable mutations appear. Thus the average number of mutations fluctuates about some low fraction of the total number of alleles. This evolution we call “purification”. However, for sexual reproduction of diploid organisms, another strategy is possible if (nearly) all mutations are recessive; we call this alternative “complementation”.

Let us take a simple model of only eight genes; the wild type or functional allele is denoted by 0, and the deleterious one by 1. The diploid genome then consists of two sequences of 0 and 1, which are called bit-strings. An example may be

```
0 0 1 0 0 1 0 0
0 0 1 0 1 0 0 0
```

which means that only one locus, the third one, is unfunctional, and all others are functional. Only if both alleles are mutated at the corresponding locus the mutations affect the phenotype. Thus genes 5 and 6 may be detrimental in future generations but not for this individual. This example is one of purification, since only one quarter of the bits are set to 1, and three quarters are in the wild form of 0.

An alternative example, for complementation instead of purification, is

```
1 1 0 1 0 1 0 0
0 0 1 0 1 0 1 1
```

where now half of the alleles are in the unfunctional state of 1, and half are still wild (0). Nevertheless, this individual does not feel any of these mutations since at no locus both alleles are set to 1. Here we have complete complementarity.

In general, one can change from one extreme to the other by measuring the heterozygosity, which is the fraction of genetic loci carrying different alleles in the two bit-strings. This heterozygosity is $2/8 = 0.25$ in the first example and $8/8 = 1.0$ in the second example. Thus purification produces a heterozygosity close to zero, and complementation a heterozygosity close to one. The Hamming distance is the number of loci which are different in the two bit-strings and thus is the heterozygosity multiplied with the number of investigated loci. (See [5] for a polymorphic generalisation to eight instead of only one bit per allele.)

We are not aware that this seemingly trivial possibility of complementarity was found earlier than [1]; in hindsight one might interpret Fig.1 in [6] as indicating an evolution towards complementarity. Now we bring some examples where it was seen in recent computer simulations [7, 8, 9, 10, 11, 12, 13, 14].

Figure 1: Sexual Penna model: populations versus recombination (= crossover) rate r for various values of the carrying capacity $K = 10^3$ (+), 10^4 ($\times$), 10^5 (*), 10^6 (squares). The gap at intermediate r shifts to smaller r for increasing K . To the left of the gap we have complementarity with many mutated bits; to the right we find Darwinian purification selection with much less bits mutated.

2 Mutations

Mutations can happen due to errors in the genome duplication during cell division, or due to external reasons like ionizing radiation. They may happen in

Figure 2: Sexual Penna model: Distribution of Hamming distances after purification (central peak) and complementation (peaks at the left and right boundaries) for $L = 64$ when only the first 40 bits are compared [7].

any cell of our body without being transferred to our children; then they are called somatic and ignored here. Alternatively, they may appear in the germline cells being transmitted to the offspring by gametes, and are called inheritable. Most of the mutations make an allele unfunctional and thus are deleterious; back mutations to the original “wild” state are rare and ignored here. We also do not deal with the rare positive mutations which transformed the first archeobacteria over thousands of million years into the present authors. Thus we deal only with deleterious inheritable mutations.

At first one may think that life would be better if mutations could be avoided. Indeed, sickness, ageing and death may come from such mutations [3]. However, if we would live forever, there would be no place for our children, and biological evolution would not have happened. Indeed, some simulations [15] in a changing environment showed an optimal mutation rate to maximise the whole population. Therefore mutational pressure, though bad for the individual, is not necessarily bad for Nature as a whole. We deal here with models where ageing or death are caused by this mutational pressure. The details of the models are less important than the emergence of complementarity in the models.

Figure 3: Illustration of complementation and gamete recognition for sexual Penna model at $r = 0, 0.001, 0.002, 0.004 \dots 0.512, 1$ from top to bottom. For small recombination rates $0 \leq r \leq 0.016$, the average Hamming distances approach 20, and then move close to 40 after gamete recognition is switched on at $t = 25,000$: Complementarity with about half of the 40 bits mutated. For $r = 0.032$ and 0.064 the population dies out, for $r = 0.128$ it does not know what it wants, and for larger r relatively few bits are mutated: purification independent of population size.

3 Some computer models

The number of bits (genes) in each bit-string (haplotype) is called L , the minimum reproduction age R , the number of births for each pair after mating B , the mutation probability per haplotype (i.e. per bit-string) M , the probability of recombination during mating r (for both father and mother; also called the crossover rate C in the literature). The Verhulst factor N/K is the probability to die because of lack of food or space, where N is the current population and K a “carrying capacity”. In the Penna model [2, 3, 16], the position of a locus corresponds to the age of an individual, and only mutations at that or at earlier positions affect the health of the individual. (New mutations are transmitted to the offspring, not to the parent.) T active mutations kill the individual at that age. Typical values are $L = 64, R = 5L/8, B = 4, M = 1, 0.001 < r < 1, T = 3$.

For the sexual Penna model, Fig. 1 shows the two regimes of low and high recombination rates. Each curve has a gap in the middle where the population dies out, for r near some critical value r_c . For low r the population survives

with the help of the above complementarity trick; for high r it survives through purification, i.e. the usual Darwinian selection of the fittest with a small number of deleterious mutations. In the right part of Fig.1, purification happens, and the population is the larger the larger K is. In the centre of Fig.1, a gap appears which shifts to the left with increasing K ; to the left of the gap, complementarity appears. (Increasing the births from $B = 2$ to $B = 4$ avoids the gap.) Fig.2 shows how the equilibrium distribution of Hamming distances looks like after purification and for complementation, when only the first $R = 40$ of 64 bits are counted.

In such a population nearly all individuals have the same bit-strings A and A' in their diploid genome, thus producing haploid gametes (ovum and sperm cells) of one type only, either A or A' . An A sperm combined with an ovum of gamete type A cannot survive with many mutations, since then even homozygous pairs of recessive alleles affect our health. The same happens with ovum and sperm cell both of type A' . But if one is of type A and one of type A' , the A - A' -zygote can survive even if half of the bits (alleles of the genome) are mutated, since there is always a one-bit in A combined with a zero-bit in A' and thus for recessive mutations the phenotype is not affected. Thus high numbers of mutations can be tolerated in this strategy. For purification, on the other hand, mutations are rare. (Warning: Sometimes changes are very slow; for $L = 512$, $R = 320$ we even had a case where the population decayed first very slowly, and after 700 million iterations very fast to extinction.)

Somewhat related is gamete recognition [10], where the ovum rejects those sperm cells for fusion into a diploid zygote whose haploid genome is too similar to the haploid genome of the ovum. This effect is beneficial if the population, due to a low recombination rate, shows complementarity. If this gamete selection is added to the sexual Penna model then complementarity survives for higher r , the population size to the left of the gap (small r) is strongly enhanced while the populations to the right of the gap (r closer to unity) barely change.

Also Fig. 3 illustrates through the Hamming distances this balance between complementation at small r and purification at large r , separated by extinction at intermediate r near r_c . For these Hamming distances we take into account the first $R = 40$ of the 64 bits. For complementarity without gamete recognition, the whole diploid population has two bit-strings A and A' , each of which with about 20 bits zero and 20 bits one. The zygotes thus are of type AA and $A'A'$ with Hamming distances 0 and of type AA' and $A'A$ with Hamming distances 40; the average Hamming distance therefore is 20, as shown in Fig. 3 near $t = 10,000$. The AA and $A'A'$ will die out in the next iteration, the AA' und $A'A$ will survive. After 25,000 iterations, gamete recognition is switched on, neither AA nor $A'A'$ is allowed to form a zygote, and the Hamming distances approach 40, as shown in the interval $26,000 \leq t \leq 100,000$. For large r and purification, the number of mutated bits and thus the Hamming distance is much smaller, and the latter shows only a small jump from 9.6 to 10.3 (independent of K) when gamete recognition is switched on. (If one of the 64 mutations is made dominant, not much changes, but nine dominant mutations lead to catastrophe [10].)

Figure 4: Mutation pressure. a: Higher mutation rates lead to a reduction of the population size and possibly extinction. $L = 64$, $R = 40$, $B = 6$, $T = 3$, $K = 1000$. (Similar to Fig.6 in [10].) b: In the left part the heterozygosity is higher than in the right part for all these curves.

Mutations are needed to drive evolution, but also endanger the survival. Fig.4 shows the effect of this mutational pressure: For $M = 2$ mutations per generation and haplotype, the population died out while for $M = 1$ extinction was avoided. For mutation pressure below $M = 1$ the population reaches nearly its maximum K . Fig. 5 shows the slow emergence of the separation of complementation (small r) and purification (large r); here the simulation time t measured in updates per individual varies from hundred (bottom curve, +) to ten million (top curve, o).

Figure 5: Time dependence for the $M = 0.2$ curve of the previous figure. For $M = 1$ equilibrium is reached somewhat faster, and r_c is about ten times higher.

4 The role of inbreeding

As has been shown in Figs. 1-3, reproduction success depends on the interplay between the intragenomic recombination rate (crossover frequency) and the size of population. Below a specific crossover rate populations prefer to complement haplotypes instead of to intensively eliminate defective alleles. In Fig.6 we show how this critical crossover rate depends on the population size [11], where r_c is defined as the crossing probability at which the number of mutations goes down drastically. In the range of two decades there is a power law relation. Nevertheless, the data shown in the plot were obtained in simulations of panmictic populations. In such populations females look for and choose randomly a sexual partner from the whole population. In Nature the process of choosing the partner is usually nonrandom and, what is more important, it is spatially restricted. Individuals are looking for partners in their neighbourhood. Thus, the effect of the population size should be considered as an effect of the inbreeding, rather. Inbreeding (coefficient) is a measure of genetic relations between individuals. If the individuals live in small “inbreeding” groups, then the inbreeding coefficient is high and there is a high probability that the sexual partners share some fragments of the same ancestral genome.

To study the effect of inbreeding, the simulation of evolution was performed on lattices; see [7] for inbreeding without lattices, by dividing the population into groups. On lattices the level of inbreeding was set by declaring the maximum

Figure 6: Log-log plot of critical recombination rate r versus population size [11]. For r below this value, complementary instead of purified haplotypes (bit-strings) are preferred.

distance where individuals can look for partners and where they can place their offspring [1]. The simulations were performed on a square lattice 1000×1000 . (Indeed, if the lattice size varies with a fixed size of the neighbourhood, r_c barely changes [11]). If the above distances within which partners are searched were set to 5, the critical crossover rate r_c was around 0.2. Populations evolving under lower recombination rate or shorter distances prefer the strategy of complementing the haplotypes while under higher recombination rate or longer distances they choose the strategy of purifying selection. Nevertheless, there are very important consequences of such a kind of choice. The complementarity evolves locally and remote subpopulations on the same lattice can have different distributions of defective alleles in their haplotypes. Using some tricks with coloring the individuals according to their genomes' structure it has been shown that the lattice is occupied by individuals with different genotypes but they are clustered. Individuals with the same genotypes occupy the same territory (see <http://www.smorfland.uni.wroc.pl/sympatry/> for some examples of simulations under different conditions).

(Further studies have shown that for sympatric speciation only the central part of the genome is responsible. The lateral part of the genome is much more polymorphic and decides on biodiversity, rather than speciation. That is why the Hamming distances between homologous haplotypes inside species are

Figure 7: Jump as a function of x at crossover probability $r = 0.01$.

noticeable. These simulations show that sympatric speciation is possible and there is no need for physical, geographical or even biological barriers for the new species to emerge inside the population of the older one.)

However, complementarity is not *always* a strong function of the population size. The results of [17] are unclear; and in the simple model of [18], Fig.7 shows about the same transition from complementation to purification, when the population size is increased by a factor of thousand. We see practically no change whether K is 5000, half a million, or five million. (In that simplification of [9], no age structure is involved, and an individual survives with probability $x^n V$ where V is the usual Verhulst factor for adults, n the number of deleterious mutations appearing in both bit-strings (chromosomes) of the diploid genome, and $x < 1$ determines the damage made by a single mutation present in both bit-strings. Males and females are distinguished. New mutations occur at gamete production and are transferred only to the baby, not to the parent. (In [18] we did not yet search for this complementarity shown now in Fig.7.)

5 Consequences

Now that the reader may have understood the complementarity principle, what are the consequences of this possible survival strategy via complementarity? Also, complementarity is an advantage of sexual reproduction compared to the asexual haploid case where complementarity is impossible. Now we discuss some

further consequences:

Sympatric Speciation: If one species splits into two within the same environment, this is called sympatric speciation. It is facilitated by complementarity through the following effect. Originally we have complementary haplotypes A and A' as discussed in section 3, leading to survivable AA' or A'A zygotes even though only about half of the alleles are of the wild type. Slowly, for part of the population A may be change into B, and simultaneously A' into the complement B' of B. After some time, AB' and A'B zygotes may no longer be survivable, and the subpopulation with B and B' has become reproductively isolated from that with A and A' haplotypes. For purification, in contrast, we have only A changing into B while keeping most alleles in the wild type, thus still keeping AB zygotes survivable because of the low number of deleterious alleles. In this way, reproductive isolation and thus speciation is easier for complementarity than for purification.

Preferred loci for recombination: Computer simulations have shown that a critical parameter for the emergence of complementarity is the recombination frequency. Human genome parameters suggest that the consequences of complementarity should be seen at least in some regions of human chromosomes, especially if one considers the uneven distribution of recombination events along them. There are so-called recombination hot spots observed where recombinations happen relatively often, and recombination deserts where recombinations are not observed at all. In these deserts complementing clusters of genes should appear. Moreover, these regions seem to be non-randomly distributed on chromosomes.

It has been noticed that the distribution of accepted recombination events in the genomes of simulated populations depends on parameters of simulations. If evolution is studied in small effective populations under relatively low recombination rates, the central parts of chromosomes start to form clusters of genes where recombinations have deleterious effect on reproduction potential. Gametes which are produced by recombinations in these regions have lower chance to produce the surviving zygotes. As a result, the recombination events in gametes which succeeded in forming the surviving individuals have a characteristic distribution, with higher recombination frequencies in the regions close to the ends of chromosomes and lower recombination rate in the central part of chromosomes, as observed in reality.

Gamete recognition: Complementation strategy assumes that two different (complementing) sequences of alleles fit to each other producing a better fitted genome. If we consider a set of chromosomes with only one pair of complementing clusters then it would be more economical to recognize which chromosome has an identical cluster and which one has a complementing cluster of genes, before two gametes fuse to form a zygote. Such systems of recognition or probing the information inside another cell are known even in the bacteria world - i.e. an entry exclusion system which prevents a bacteria to engage in conjugational process if a partner cell already possesses genetic information to be transferred [19, 10]. It is suggested that in humans the Major Histocompatibility Complex (MHC) can play such a role in preselection of partners [20, 8].

Figure 8: Comparison of simulated critical recombination rate r_c for effective population size 100, 200, 1000 (from top to bottom) for chromosomes containing L genes with parameters of human chromosomes. For real chromosomes (+), data show the average number of crossovers per meiosis (y-axis) against the number of genes per chromosome (x-axis). Thus human genomic data suggest that at least some parts of our genome could evolve under complementing regime.

This complex alone is not enough to guarantee the fusion of complementing haplotypes. The mechanism should be located at the level of gametes and, to be efficient, it should be independent for different pairs of chromosomes nestling the complementing clusters of genes. There is a group of genes which could fulfil such a role - Olfactory Receptor genes (OR). This is the largest gene family in the human genome composed of almost 1000 genes and pseudogenes, clustered in many different groups located on almost all chromosomes (excluding Y) and at least some of these genes are expressed during spermatogenesis [21]. If we assume that each of our 22 pairs of autosomes has complementing clusters of genes, then an ovum would have extremely low chance to find a fully complementing sperm cell (2^{-22}). If an ovum could choose such a sperm cell, it should have a pool of at least 2^{-22} sperm cells. In fact this pool seems about 10 times larger.

6 Discussion

The destruction of complementarity by high crossover rates r is easy to understand: The delicate emergence of two complementary bit-strings A and A' in the whole population is destroyed for each individual where crossover in the middle of the chromosome leads to massive changes in the chromosome structure. The dependence on the (effective) size of the population seems more complicated. It is also possible that r_c depends on the size of the chromosome, or that in one genome some chromosomes should complement while others follow purification [13]. Fig.8 compares such simulations with reality; the order of magnitude seems to be realistic. Complementarity may also affect the distribution of crossing points along the bit-strings [12, 14]. Complementarity requires that whole sequences of neighbouring genes are transmitted together after recombination; if for each locus the transmitted allele is selected randomly one would hardly find nearly complementary haplotypes [14]. In any case, the details of the models are not important; our important point is that allele complementarity is in principle plausible, was found in some computer simulations, and should be checked in reality.
